ABSTRACT: A series of 5-hydroxy-isoflavones—genistein, biochanin A, prunetin, and 4',7-dimethoxygenistein—have been studied by surface-enhanced Raman spectroscopy (SERS). Citrate reduced silver colloids were employed as a standard technique to measure SER spectra over a range of pH and concentrations. Density functional theory calculations were used to assist in determining the mode of interaction of isoflavones with the silver nanoparticles. It is revealed that biochanin A and prunetin interact with the silver nanoparticles upon deprotonation of the 7- and the 4'-OH groups, respectively, to show SERS activity. Correlations of their spectra with SERS of genistein strongly support the presence of multiple interaction modes involving both of the OH groups in genistein, in a similar manner to daidzein. Surprisingly, however, under these conditions, the 5-OH group was found to be noninteractive as revealed by attempts to measure SERS of 4',7-dimethoxygenistein. This was attributed partly to the low solubility and, more importantly, to the influence of steric hindrance, caused by the position of the pendant phenyl ring, which prevented interaction with the Ag colloid surface. These results complement recent work on daidzein and formononetin and provide further insight into understanding the SER spectra of isoflavones.

■ INTRODUCTION

Since the discovery of the enhancement of the Raman signal from pyridine adsorbed on a roughened electrode,¹ surface-enhanced Raman (SER) spectroscopy, or SERS, has become a prolific field of study with enormous advantages offered over conventional normal Raman (NR) spectroscopy. A combination enhancements arising from an electromagnetic mechanism (EM) due to localized surface plasmon resonance, and chemical mechanisms (CM) resulting from the molecule–metal interactions are accepted as the two major contributors to the Raman signal enhancements.^{2–4} While SERS may be regarded as universal for species in the proximity of the metal under the EM,⁵ the enhancements are greatest for the species closest to the metal surface. This is because the strength of electric field due to surface plasmon resonance is proportional to r^{-3} (r = distance) from the surface,⁶ which creates a strong distance dependence on the EM enhancement (r^{-10}).⁷ Moreover, CM, or specifically, the charge transfer (CT)⁸ and the ground state nonresonant (CHEM)⁹ enhancements require the molecule–metal interactions as a prerequisite. Thus, species with a stronger affinity toward the metal surface and preferentially adsorb will be subject to greater enhancement. As a consequence, the study of SERS on a new target begins with the search for a set of conditions that optimizes analyte adsorption, which tend to be molecule specific depending on the nature of the interaction.

We have recently reported a detailed SERS analysis on daidzein (4',7-dihydroxyisoflavone) and formononetin (4'-methoxy-7-hydroxyisoflavone), which are two isoflavones that belong to a broader class of chemicals known as phytoestrogens.¹⁰ The properties and interactions of this class of chemicals are of interest given the increasing awareness of their role in human health and their growing use as nutraceuticals. A number of potential health benefits have been identified including the prevention or reduced risk of cancer, heart disease, osteoporosis, and postmenopausal symptoms,^{11–15} while conflicting reports exist on its role in increased thyroid disorders¹⁶ and impaired male fertility.^{17,18} Here, we examine four related isoflavones: genistein (4',5,7-trihydroxyisoflavone), biochanin A (5,7-dihydroxy-4'-methoxyisoflavone), prunetin (4',5-dihydroxy-7-methoxyisoflavone), and 4',7-dimethoxygenistein (5-hydroxy-4',7-dimethoxyisoflavone), which all possess a hydroxyl group at the C₅ position (Figure 1). A group of structurally related molecules, flavones, which have the phenol ring attached to the C₂ position of the chromone system, have also been the subject of previous SERS studies by several groups.^{19–21} SERS of genistein and its derivatives, on the other hand, have not been published

anywhere to the best of our knowledge, apart from a paper by Bhandari et al.,²² who used a selection of flavonoids, including daidzein and genistein, to test the efficacy of a new SERS active extraction filter to preconcentrate analytes and acquire their spectra.

Owing to its growing importance, various spectroscopic methods such as UV–visible,²³ infrared (IR),^{23,24} and NR spectroscopy²⁵ have been used to study, in particular, genistein, due to its higher occurrence in the human diet as a major isoflavone found in soy beans. It is the aim of this study to extend the previous SERS study of isoflavones, and to lay the framework for possible future application to phytoestrogen analysis. In our previous study, it was revealed that the OH substitution pattern on the isoflavone backbone has a great influence on its interaction with the metal surface, and as a consequence, manifests a significant variation in the spectral profile.¹⁰ The nature of this interaction was successfully probed by substituting one of the OH groups with a methoxy group, which in effect, eliminated one site of interaction, combined with density functional theory (DFT) calculations.

Computational methods have been used extensively to assist in the understanding of SERS. Within the static, time-independent methods, NR spectral simulations facilitate assignments on the experimental NR spectra that are useful in interpreting the SERS spectra.^{26–28} It has also been demonstrated that the simple addition of metal adatom (M/M^{n+}) is able to provide further insight into SERS. For example, energetically favorable metal–analyte complexes can be identified^{29–31} and used to simulate the Raman spectra^{32–36} and may be extended to incorporate metal clusters.^{37–39} The latter techniques are able to provide some theoretical insight into wavenumber shifts on analyte–metal interaction^{32–34,36,38} and, within limits, intensities,^{37–39} which is an invaluable tool in SERS analysis. Furthering the approach to time-dependent (TD) theories such as TD-DFT can take these calculations beyond the static limit, enabling the additional inclusion of enhancements arising from EM (with larger clusters such as Ag₂₀), CT, and molecular resonance enhancements.^{40–43}

In this paper, we adopt the use of static Raman calculations of the molecules complexed with adatoms (Ag^0 and Ag^+) to analyze the SERS of genistein and its derivatives. Due to the number of molecules examined in this study, the SERS analysis of the isoflavones only is treated in this paper, whereas the NR and IR analyses that form the necessary background to the work have been published separately.⁴⁴ The combined approach of

experimental and computational investigations demonstrates another multimodal interaction mechanism for genistein, supported by comparison with its methoxy derivatives.

EXPERIMENTAL SECTION

Materials and Reagents. Genistein (GSTN, $\geq 99\%$) was purchased from LC Laboratories (MA, U.S.A.), Biochanin A (BCHA, 97.4%) and Prunetin (PRTN, $\geq 98.0\%$) are from Sigma-Aldrich (New South Wales, Australia), and 4',7-dimethoxygenistein (DMG, 98%) is from ChemCollect GmbH (Remscheid, Germany). Stock solutions of 2.0 mM concentration were prepared in absolute ethanol ($\geq 99.7\%$ purity, Merck, Victoria, Australia) and working standards (10–100 μM) were prepared by further dilution of the stock solution. In the case of DMG, a 100 μM solution was directly prepared due to its poor solubility.

All glassware were cleaned by treatment with a 10% Pierce PCC-54 detergent solution (Thermo Fisher Scientific Inc., IL, U.S.A.), an alternative reported to be as effective as aqua regia in cleaning the glassware for SERS purposes.^{19,45} They were subsequently sonicated for 5 min each in acetone and methanol and finally rinsed with 18.2 M Ω ultrapure water.

Silver (Ag) colloids used in the SERS measurements were prepared by reduction of silver nitrate ($\geq 99.9999\%$ AgNO₃, Sigma-Aldrich, New South Wales, Australia) with citrate as reported by Lee and Meisel.⁴⁶ The absorption spectrum was acquired periodically to monitor the colloid aggregation during synthesis. The colloid thus prepared had a turbid gray appearance with a $\lambda_{\max} = 414$ nm.

Raman Spectroscopy and SERS Acquisition. All Raman and SERS measurements were carried out on a Renishaw Raman Microspectrometer RM2000 (Renishaw, New Mills, UK) equipped with a 782 nm NIR excitation laser and a thermo-electrical cooled CCD detector, between 1800 and 200 cm^{-1} . The 782 nm laser excitation was used to avoid any potential sample degradation from shorter wavelength lasers. The laser power measured at the sample was usually less than 1 mW, with 1×10 s accumulation. The normal Raman (NR) spectra were obtained from the powder samples as purchased (polycrystalline solid) and also from the solid dried from the stock ethanolic solutions (dried solid).

SER spectra were obtained with citrate-reduced Ag colloids in a manner previously described.¹⁰ Briefly, the spectra were acquired from a drop of premixed 2:1:2 Ag colloid solution/sample solution (10–100 μM)/0.2 M KNO₃ aqueous solution mixture, with the laser focused by a 20 \times or 50 \times objective on the aggregates identified in the droplet. This aggregate formation and targeting were found to be critical in obtaining optimal SERS signals, typically accumulating on the edge of the droplets. Other anions including SO₄²⁻ (as Na₂SO₄), Cl⁻ (as NaCl) and ClO₄⁻ (as NaClO₄) were additionally tested as aggregating agents in the study. NO₃⁻ was the first anion of choice for consistency with previous work^{10,19,20} and was found to be effective for GSTN and PRTN. However, the spectral quality from BCHA was poor and was improved by using SO₄²⁻, which interestingly was similar to the behavior of formononetin, the 4'-methoxy derivative of daidzein. For SERS in acidic conditions, the pH of the aggregating agent was initially varied by diluting a 0.2 M HNO₃ solution with 0.2 M KNO₃ to keep the NO₃⁻ concentration constant over the series. Alkaline solutions were prepared by appropriately diluting a 0.2 M KOH solution. Where SO₄²⁻ was used, H₂SO₄ or NaOH solution was appropriately diluted with 0.2 M Na₂SO₄ to

keep the SO_4^{2-} concentration constant over the series. It should be noted that the reported pH is that of the final mixture used for SERS measurements, which contains 20% ethanol (v/v) as solvent for the analytes. The pH was measured before and after the addition of the organic component and the increase (as expected) was typically less than 0.3 pH units, which is much smaller than the pK_a differences of the OH groups of interest and was deemed negligible.

Computational Chemistry. In order to aid assignment of the observed SERS bands, normal vibrational modes and Raman activities of the molecules were computed and then correlated with the corresponding predictions for the complexed species. The details of the conformational search and the NR spectrum calculations are described elsewhere.⁴⁴ In brief, all stable conformers identified using the AM1 semiempirical method in the *Hyperchem* software (Version 8.0.4, Hypercube Inc., Gainesville FL, U.S.A.) were further optimized with DFT at the B3LYP level with 6-31+G(d) basis set using the *Gaussian 03* software⁴⁷ (Gaussian, Inc., Wallingford CT, U.S.A.).

To evaluate spectral shifts induced by complexation to the silver surface, calculations were performed on systems containing silver (Ag^0) atoms and ions (Ag^+). A mixed basis set was used where a 6-31+G(d) basis set was used for carbon, hydrogen, and oxygen and the SDD basis set with Stuttgart pseudopotentials⁴⁸ for silver. The lowest energy conformer identified in the neutral molecule was used for the modeling of the complex. However, in practice, the small energy differences ($\Delta E < 3.0 \text{ kJ mol}^{-1}$ predicted in vacuo) would likely be negligible in solution, except for 5-OH orientation ($\Delta E > 50 \text{ kJ mol}^{-1}$) due to the strong internal hydrogen bonding to the nearby carbonyl group.^{44,49,50} Energy barriers to torsional rotations at the $\text{Ag}^{0/+}$ attachment site were calculated using the appropriate conformations by potential energy scans with a loose convergence criterion in the *Gaussian 03* software.

Normal mode vibrations and Raman activities were computed on the final optimized structures and were used to simulate the experimental spectra, where the final intensities are calculated for 782 nm excitation ($\bar{\nu}_0 = 12787 \text{ cm}^{-1}$) using the formula⁵¹

$$I_i = \frac{f(\bar{\nu}_0 - \bar{\nu}_i)^4 S_i}{\bar{\nu}_i \left[1 - \exp\left(-\frac{hc\bar{\nu}_i}{kT}\right) \right]} \quad (1)$$

where S_i is the calculated Raman activity for the i -th mode at $\bar{\nu}_i \text{ cm}^{-1}$; h , c , and k are the fundamental constants, and f is a normalization factor. The temperature T was assumed to be 298 K. A uniform scaling factor (SF) of 0.979 was used to be consistent with earlier work on daidzein and formononetin. The resulting rms values are quoted with the appropriate tables for the molecules. Scaling factors are commonly applied to calculated vibrational frequencies to correct for, among several factors, anharmonicity of the potential energy surface.⁵² Note that the simulated Raman spectra in the figures were generated by applying 8 cm^{-1} Lorentzian broadening to the wavenumber values. As a result, the labeled values on the figures may be slightly shifted from the calculated values in the tables.

RESULTS AND DISCUSSION

As has been highlighted in a large number of SERS studies, the adsorption of the analyte on to the rough metal surface is often the key to successful SERS observation.^{53–55} In many cases, there is a delicate equilibrium with other electrolyte components coexisting in the SERS solution. The analyte must therefore have

a higher affinity toward the metal surface than other electrolyte species. Unmodified citrate reduced silver colloids are covered with remnant citrate on the metal surface,⁵⁴ which helps to attract positively charged targets such as rhodamine 6G to facilitate their SERS activity. In daidzein and formononetin which are weakly acidic, we observed the pH dependent nature of their SERS activity, where it was concluded that they needed to be deprotonated in order to adsorb preferentially over remnant citrate on to the silver surface.¹⁰ Accordingly, interaction was found to occur via the sites of deprotonation, the acidic hydroxyl ($-\text{OH}$) groups, 7-OH in formononetin and additionally at 4'-OH in

^a Labels used: vs, very strong; s, strong; m, medium; w, weak; vw, very weak; br, broad; and sh, shoulder. ^b All DFT predicted wavenumbers have been scaled uniformly by a factor of 0.9790. ^c Notations used: ν = stretch, δ = in plane bend, γ = out of plane bend, τ = torsion. Where a ring mode closely resembles those of benzene as shown by Alcolea Palafox,⁶⁷ Wilson numbering of the mode (1–20b) is shown in the superscript following a general description of the mode in parentheses, whereas the subscript indicates the corresponding ring (A, B, or C) and where applicable, direction (α , β , or γ as in Figure 1). Some modes are slightly different due to ring substituents and preference is then given to a more accurate description of the analyte complex. ^d 1307 cm⁻¹ band was deconvoluted by Lorentzian curve fit to 1314, 1307, 1300, and 1293 cm⁻¹ (data not shown). The two modes with significant $\nu(\text{C}_7-\text{O})$ contribution are listed here. ^e Assigned to two merged modes. ^f The NR predicted position is highly sensitive to the selected conformers. ^g Torsional components (independent) experiencing the largest displacements according to the Gaussian 03 program output are listed. ^h Output lists the internal hydrogen bonding “stretch” between 5-OH hydrogen and the carbonyl oxygen to be the largest contribution. ⁱ The motions appear as (CCC + CH). ^j Vibration degenerate according to Scherer. ^k Using Suter’s description for phenolate anion,⁵⁷ $\nu_5 = 1476 \text{ cm}^{-1}$.

daidzein. Such behavior supports the description of anion adsorption on citrate reduced silver colloids as the competitive binding by Bell et al.⁵³

Surface Enhanced Raman Spectroscopy of Biochanin A. BCHA has two OH groups at the C₅ and C₇ positions that can potentially deprotonate to give negatively charged species. Comparing the NR and SER spectra of BCHA (Figure 2), although many peaks appear to remain well aligned (e.g., 1619, 1518, 1185, 1145, 881, 773, and 566 cm⁻¹ in the NR spectrum), a

significant change in the spectrum indicative of a chemical interaction with the surface is clearly evident. As was previously established with formononetin,¹⁰ the 7-OH (pK_a ~7.2)⁵⁶ is capable of interacting with the silver surface upon deprotonation and with a similar behavior observed in the pH dependence (Figure 3), the initial study was concerned with this site of interaction. Following a potential energy scan about the [ring A]–C₇–O⁻–Ag⁺ torsion, it was found to have an energy barrier comparatively higher (ca. 7.3 kJ mol⁻¹) than in the case of

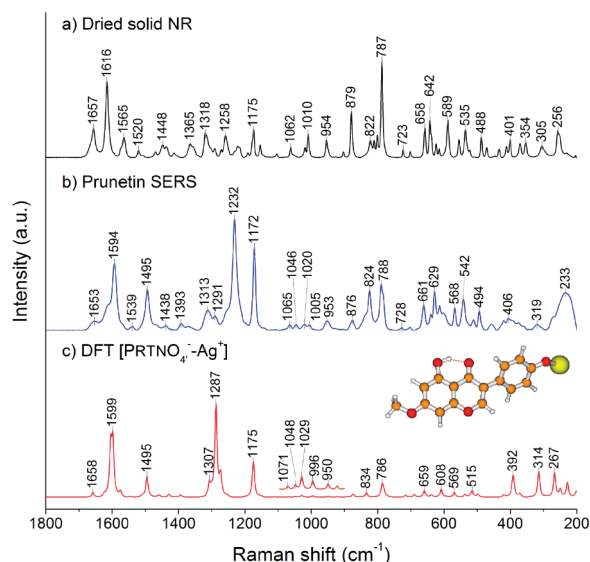

Figure 4. Experimental (a) dried solid-state Raman spectrum (from 2 mM solution), (b) SER spectrum of PRTN (pH 10.2), and (c) simulated Raman spectrum of the PRTN- Ag^+ complex, $[\text{PRTNO}_4^- - \text{Ag}^+]$.

formononetin ($<4 \text{ kJ mol}^{-1}$) and was therefore expected to be more significant in its attachment orientation. Thus, the SER spectral assignment for BCHA is based on the lowest energy conformer, with $\text{Ag}^+ - \text{O}^-$ bond distance and $\text{Ag}^+ - \text{O}^- - [\text{ring A}]$ interior and dihedral angles of 2.08 \AA , 121° , and 6° respectively: the Ag^+ slightly offset from the plane of ring A. The predicted Raman spectrum of the complex $[\text{BCHAO}_7^- - \text{Ag}^+]$ is shown in Figure 2 and the SERS band assignment based on this structure is in Table 1. The rms deviation value according to the table is 10.7 cm^{-1} .

Vibrational analysis of the phenolate anion⁵⁷ and its Li^+ and Na^+ complexes⁵⁸ has shown that the ring stretching mode (19a) at 1483 cm^{-1} ⁵⁹ (referred to as ν_5 in Suter et al.⁶⁰ and henceforth ν_5 -type in this article) exhibits some C–O stretching character and is shifted from 1501 cm^{-1} in the neutral phenol.⁶¹ We observed a similar shift in SERS of phenol, from 1501 cm^{-1} in the neutral solid-state NR to 1473 cm^{-1} in SERS, indicating its interaction as a phenolate (data not shown). Moreover, the mode with the strongest C–O stretching character in phenolate (ν_6) was found to be highly sensitive to the intermolecular interactions with Na^+ and Li^+ .⁵⁸ We have found a similar behavior also with Ag^+ , where in this case the length and torsion affected the DFT predicted C–O stretching wavenumber ($\Delta_{\text{max}} \approx 40 \text{ cm}^{-1}$), whereas ν_5 remained consistent ($\Delta_{\text{max}} \approx 15 \text{ cm}^{-1}$).

In the SER spectrum of BCHA, the ν_5 -type band of ring A at 1476 cm^{-1} is a strong evidence for a $\text{C}_7 - \text{O}^- - \text{Ag}^+$ interaction, supported by the observations on phenol, and with a similar shift of -32 cm^{-1} predicted by DFT (band not observed in experimental NR). On the other hand, the same band in ring B at 1514 cm^{-1} has only a modest shift from 1518 cm^{-1} in the NR since the methoxy group is not capable of interacting in the same manner. For the ν_6 -type band, the 1307 cm^{-1} band in BCHA is expected to have a contribution from the $\text{C}_7 - \text{O}$ stretching mode, and the breadth may be partially accounted for by the sensitive nature of this mode to the interaction geometry. However, we could not isolate a single mode appropriate for such a simple description due to coupling to many other

Figure 5. pH dependent SERS of PRTN. Variation in the relative intensities can be observed at low pH, which reappears in highly alkaline solutions.

vibrations of the complex, and the band itself has several overlapping peaks: 1314 , 1307 , 1300 , and 1293 cm^{-1} . Finally, an intense, broad band appears in the $210\text{--}240 \text{ cm}^{-1}$ region for phenol and BCHA (and also for other derivatives). This was not studied in detail due to the presence of the colloid background but are most likely to arise from vibrations involving $\nu(\text{Ag}-\text{O})$ of the probe molecules.⁶²

An alternative site of interaction with the metal surface is at the 5-OH position, which was expected to chelate upon deprotonation. However, DFT predictions on species chelated to Ag^+ do not agree with the experimental SER spectrum (Supporting Information, Figure S1). For reasons that will also be discussed later, it appears that 5-OH does not contribute to analyte–metal interactions under these conditions.

Surface Enhanced Raman Spectroscopy of Prunetin. The complement of BCHA is prunetin (PRTN), where the 7-OH group is replaced with a methoxy group instead of the 4'-OH, thus blocking the $\text{C}_7 - \text{O}$ while permitting the $\text{C}_4' - \text{O}$ to interact with the silver surface. The 5-OH remains unchanged and potentially available for further interactions.

As with BCHA, there is a dramatic change between the NR and SER spectra of PRTN, indicative of a structural change upon interaction with the surface (Figure 4). Although the pK_a of the 4'-OH group is ca. 8.3,⁶³ the SER spectrum of PRTN can be observed at pH 6.0 through to pH 11.2, with the major bands appearing in all spectra (Figure 5). It is well-known that the pK_a may be lowered in the presence of an interacting metal, and this may be the reason for the SERS observation at lower pH. Accordingly, the simple Ag^+ interaction DFT model on the PRTN anion deprotonated at 4'-OH was studied. Such optimized models of PRTN complex $[\text{PRTNO}_4^- - \text{Ag}^+]$ had an $\text{Ag}^+ - \text{O}^-$ bond distance of $2.07\text{--}2.08 \text{ \AA}$ and an $\text{Ag}^+ - \text{O}^- - \text{C}_4'$ angle of $121\text{--}125^\circ$, depending on the dihedral angle about $\text{Ag}^+ - \text{O}_4' - [\text{ring B}]$. The torsional energy barrier about this dihedral angle was less than 3 kJ mol^{-1} , which was considered to

^a Labels and notations as per Table 1. ^b All DFT predicted wavenumbers have been scaled uniformly by a factor of 0.9790. ^c Some modes are slightly different to the equivalent NR description. In such cases, preference is given to a more accurate description of the analyte complex. ^d Shoulder peak revealed by Lorentzian curve fitting. ^e Assigned to two merged modes. ^f NR assignment is tentative. ^g See Table 1. ^h The motions appear as (CCC + CH). ⁱ Vibration degenerate according to Scherer. ^j NR equivalent modes are slightly different due to either $\nu(\text{Ag}-\text{O}_4')$ contribution or $\tau(\text{C}_{\text{Me}}\text{OC}_6\text{C}_7)$ orientation ($\Delta E \approx 1 \text{ kJ mol}^{-1}$). ^k Using Suter's description⁵⁷ for phenolate anion: $\nu_4 = 1594 \text{ cm}^{-1}$, $\nu_5 = 1495 \text{ cm}^{-1}$, and $\nu_6 = 1232 \text{ cm}^{-1}$.

be insignificant and thus the DFT prediction was selected based on rms of peak positions. In addition, some relative intensity changes were observed as the pH is varied from acidic to alkaline conditions that could not be easily accounted for. It is possible that there may be orientation changes on the surface, possibly related to the third deprotonation of the surface citrate ($\text{pK}_{\text{a}3}$ 6.41).⁶⁴ In order to assign the observed bands, the average spectrum was used for the analysis.

The best overall match was obtained from a complex with bond length, angle, and torsion of 2.07 Å, 123°, and 65.3°,

respectively, and its comparison is shown in Figure 4. The SERS band assignment based on this model is presented in Table 2. As can be seen, the phenolic ν_5 -type mode of the B-ring is shifted from 1520 cm⁻¹ in the NR to 1495 cm⁻¹ in SERS (1524 → 1495 cm⁻¹ in DFT), which supports the interaction of C₄'-O⁻ with the Ag surface. Other major bands are well reproduced with the DFT calculation, with 1594 (1605 in DFT, but part of overlapping bands), 1313 (1307), 1172 (1175), and 788 (787, overlap with 782) cm⁻¹ in good agreement. The 1232 cm⁻¹ band is, however, poorly predicted at 1287 cm⁻¹, which is

Figure 6. Spectra of DMG under (a) SERS conditions, (b) polycrystalline solid-state NR, and (c) dried solid-state NR (from 100 μM solution). Only a small variation is observed over the pH range in SERS, whereas the major bands are still observable at highly acidic pH.

assigned to the sensitive ν_6 -type stretching of the $\text{C}_4'-\text{O}$. The final rms value for the assignments in Table 2 was 11.37 cm^{-1} (or 7.44 without the $\text{C}-\text{O}$ stretch).

Again, deprotonation and the subsequent interaction with $\text{Ag}^{0/+}$ at the 5-OH position result in different predicted spectra which are not in agreement with the experimental spectrum, and thus not included in the analysis.

SERS Attempt on 4',7-Dimethoxygenistein. In order to determine whether the 5-hydroxyisoflavones are also interacting with Ag surface via the 5-OH site, another derivative of GSTN with the 4'- and 7-OH groups both substituted with a methoxy group was studied. This compound, 4',7-dimethoxygenistein (DMG), has only one possible site of interaction at the 5-OH. Due to the strong internal hydrogen bonding, it has a considerably high pK_a value of 11.0 (in 10% ethanol solution). Related compounds 5-hydroxyflavone and GSTN have pK_a values of 11.5⁶³ and 13.1, respectively where the latter has a higher value because this deprotonation process involves the formation of a trianionic species.

Previous studies on 5-hydroxyflavone¹⁹ and alizarin,^{65,66} molecules that share the same structural motif (OH with β -carbonyl group), have revealed that chelation to the Ag surface is likely to occur following 5-OH deprotonation. Alizarin in particular, shows a remarkable affinity to the Ag surface such that it can be observed in SERS at a much lower pH of 5.5 than its pK_a (11.5 in DMSO/water), providing evidence that the acidity of a proton can be dramatically changed in the presence of the Ag surface. Furthermore, DFT prediction of the Raman spectrum of 5-hydroxyflavone- Ag^+ chelation product agrees convincingly with the

experimental SER spectrum with a predicted $\nu_{\text{asym}}(\text{C}=\text{O}, \text{C}-\text{O}^-)$, which is also coupled to an in-plane ring AC stretch, at 1433 cm^{-1} (1431 cm^{-1} by experiment¹⁹). Although Teslova et al. proposed a slightly different assignment based on the free, neutral molecule (as ring A, CC stretch),¹⁹ the deprotonated model follows strongly from the accumulated evidence with our work on isoflavones.¹⁰ It was thus expected that the 5-OH in DMG may also deprotonate and form a chelating product, $\text{DMG}-\text{Ag}^+$, with the surface even at a moderate pH, with the $\nu_{\text{asym}}(\text{C}=\text{O}, \text{C}-\text{O}^-)$ predicted at 1415 cm^{-1} (Supporting Information, Figure S3).

However, the experimental spectra of DMG under SERS conditions do not support the presence of a chelating product. As shown in Figure 6, in spectra over the pH range of 3.7 and 11.2, it is clear that the SER spectral profile of DMG is significantly different than any of the other isoflavones studied here. At very acidic pH (3.7), where all other isoflavones do not show SERS activity, the DMG marker band at 778 cm^{-1} is still observed. The change in the spectrum at pH 11.2 shows the loss of the analyte spectrum with only a band assignable to NO_3^- at 1062 cm^{-1} (confirmed by comparing with SO_4^{2-} aggregating agent at 982 cm^{-1}) and some colloid background. The latter behavior was seen in other isoflavones and has been attributed to the high concentration of hydroxides in the alkaline environment, forming oxides on the silver surface. The S/N levels of the spectra are ca. 2 orders of magnitude lower on average than at lower pH, and spectral interferences from the colloid are overwhelmingly present. Increasing the concentration above 20 μM only resulted in the precipitation of the analyte due to its poor solubility.

In fact, the NR (polycrystalline solid) and SER spectra of DMG are very similar with only minor band shifts, and the bands are sharp compared to the other isoflavone spectra. In consideration of this resemblance and the above factors, it is proposed that the spectra acquired are simply of DMG molecules that have physically adsorbed in the vicinity of the Ag nanoparticles due to its poor solubility in the solvent. The nanoparticles therefore remain coated with the citrate, and DMG molecules do not chemically interact with the metal surface. The combination of the inability to displace citrate from the surface and the lack of interaction would result in a low SERS enhancement. Based on this assumption, a tentative assignment of the SER spectrum is shown in Table 3, correlating directly to the NR spectrum and to the DFT predictions on the free molecule (rms = 7.1 cm^{-1}). A possible reason contributing to this result is steric hindrance caused by the B ring which prevents effective interaction between the hydroxyl group and the Ag surface. However, further investigation would be necessary to reach a definitive conclusion. It should also be noted here that the NR spectrum of the polycrystalline solid is slightly different to that of the dried solid (Figure 6), much like the behavior of GSTN.⁴⁴

This result would imply that BCHA and PRTN are unlikely to interact at the 5-OH site. Spectral evidence in the experimental SERS is inconclusive, since the symmetric and antisymmetric $\nu(\text{C}_4=\text{O}, \text{C}_5-\text{O}^-)$, which are predicted at 1569 and 1417 cm^{-1} respectively for the chelating PRTN are both missing from the SER spectra (Supporting Information Figure S2). The $\gamma(5-\text{OH})$ mode, predicted to be present at 876 cm^{-1} if the compound does not deprotonate at the C_5 position is obscured by more intense in-plane ring C and B vibrational modes, predicted at 875 cm^{-1} and observed at 876 cm^{-1} . The $\delta(5-\text{OH})$ mode is coupled to various in-plane ring vibrations and cannot be isolated in the

Figure 7. pH dependent SERS of GSTN. Similar behavior to the derivatives BCHA and PRTN is observed.

spectra. A similar argument can be drawn for BCHA. It is thus proposed that the primary interaction is at the deprotonated OH groups at the C₇ and C₄' positions of BCHA and PRTN, respectively, with negligible contribution from the chelating species.

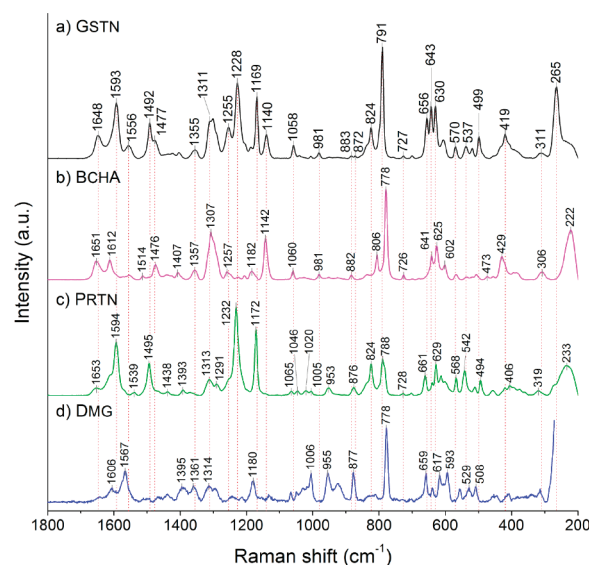

Figure 8. SERS comparison of (a) GSTN, (b) BCHA, (c) PRTN, and (d) DMG. An excellent correlation exists between the spectra of GSTN and their derivatives except for DMG where an alternative adsorption mechanism is proposed.

Putting the Picture Together: SERS of Genistein. Finally, the SER spectra of GSTN at various pH are shown in Figure 7. As in the derivatives BCHA and PRTN, the solid phase NR and the SER spectra have significantly different appearances. Of the three hydroxyl groups ($\text{p}K_{\text{a}1}$ 7.2 (7-OH), $\text{p}K_{\text{a}2}$ 10.0 (4'-OH), $\text{p}K_{\text{a}3}$ 13.1 (5-OH)),⁵⁶ the 7-OH and 4'-OH groups are able to interact with the surface as demonstrated with BCHA and PRTN

^aThe corresponding BCHA or PRTN bands are also shown. ^bLabels and notations as per Table 1. ^cAll DFT predicted wavenumbers have been scaled uniformly by a factor of 0.9790. ^dSome modes are slightly different to the equivalent NR description. In such cases, preference is given to a more accurate description of the analyte complex. ^eThe equivalent experimental SERS band of BCHA or PRTN. As per NR modes, some may be different and preference is given to the appropriate GSTN complex. ^fThe NR peaks are those observed from a dried solid sample, except those marked with *, which is from the IR spectrum. ^gThe shifts here appear to be in the opposite directions but can unambiguously be assigned to this mode relative to the surrounding peaks. The same behavior is observed in BCHA. ^hHidden peak revealed by a curve fit and the second derivative spectrum. ⁱSee Table 1. ^jOutput lists the internal hydrogen bonding "stretch" between S-OH hydrogen and the carbonyl oxygen to be the largest contribution. ^kNR equivalent modes are slightly different due to $\nu(\text{Ag}-\text{O}_{\text{Ar}})$ contribution. ^lThis mode is slightly coupled to an adjacent mode predicted at 617 cm⁻¹. ^mAppears like $\delta(\text{CCC})_{\text{C}}^{1,n}$ Using Suter's description⁵⁷ for phenolate anion: $\nu_4 = 1593$ cm⁻¹, $\nu_5 = 1492$ and 1477 cm⁻¹, and $\nu_6 = 1228$ cm⁻¹. ⁿThe motions appear as (CCC + CH). ^oVibration degenerate according to Scherer.

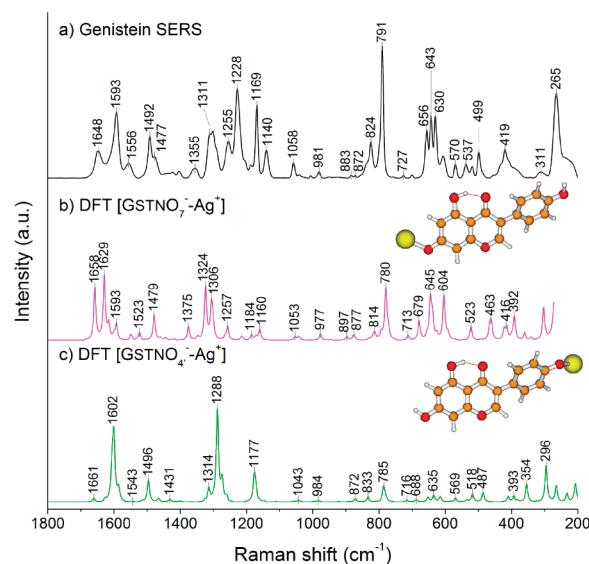

Figure 9. Experimental SERS of GSTN (a) and the DFT simulated Raman spectra of the deprotonated GSTN-Ag⁺ complex interacting via (b) C₇-O⁻ and (c) C₄'-O⁻ oxygens, labeled [GSTNO₇⁻-Ag⁺] and [GSTNO₄⁻-Ag⁺], respectively.

respectively, whereas S-OH appears to be inactive on the surface as a binding site. Accordingly, the SER spectrum of GSTN appears almost as a sum of the spectra of the two derivatives, facilitating a comparative assignment of the observed bands (Figure 8 and Table 4). Characteristic peaks at 1492 and 1477 cm⁻¹ of the phenolic ν_5 -type modes at ring B (C₄'-O⁻) and ring A (C₇-O⁻) clearly show the anionic nature of GSTN as it interacts with the metal surface. The prominent peaks of BCHA at 1651, 1476, 1307 (overlapped bands), 1142, 1060, and 641 cm⁻¹ correlate convincingly with 1648, 1477, 1311 (overlapped bands), 1140, 1058, and 643 cm⁻¹ peaks of GSTN, respectively. These peaks were assigned using the GSTN anion-Ag⁺ complex [GSTNO₇⁻-Ag⁺] as shown in Figure 9, directly analogous to the BCHA anion-Ag⁺ complex, [BCHAO₇⁻-Ag⁺]. Similarly, peaks assignable to the alternative [GSTNO₄⁻-Ag⁺] complex are present at 1593, 1492, 1228 (poorly predicted), 1169, and 824 cm⁻¹, all of which feature dominantly in SERS of PRTN at 1594, 1495, 1232, 1172, and 824 cm⁻¹, respectively. This behavior is also in agreement with the daidzein spectrum, which shows multiple interactions with the surface.¹⁰ The final rms error based on the assignments through the two proposed complexes was 13.5 cm⁻¹, or 10.6 cm⁻¹ without the sensitive C-O stretch as in PRTN. It should be noted that the simultaneous attachment of Ag^{0/+} at the two positions did not improve the agreement between the DFT prediction and the experimental SERS, and it is thus proposed that the two interactions occur independently.

CONCLUSION

Surface-enhanced Raman spectroscopy characterization of isoflavones have been extended to include 5-hydroxy substituted analogues; genistein, biochanin A, prunetin, and 4',7-dimethoxygenistein. The SER spectral assignments have been achieved by means of a comparative analysis of the four isoflavones, as well as phenol and other flavonoid compounds. DFT calculations on the analyte-metal complex have again been demonstrated to be a

useful approach to understanding the interfacial interactions in SERS analysis through predicted wavenumber shifts. Through this work, we have identified the interaction of the hydroxyisoflavones as anions, deprotonated at the C₇- and C_{4'}-OH groups, whereas the C₅-OH group is found to have little contribution to the analyte-metal interaction in SERS. Although more research may be required before a reliable application of SERS for isoflavones can be realized, this work sheds light on the interaction of isoflavones with Ag nanoparticles and shows an effective approach to SERS analysis of this particular group of molecules.
